13. ABSTRACT (Maximum 200 words)  Munitions use on military lands is of keen environmental interest primarily due to the potential for contamination from unexploded ordnance (UXO) constituents. Explosive fillers such as Trinitrotoluene (TNT), Royal Demolition Explosive (RDX), and High Melting Explosive(HMX) are subject to environmental fate and transport congruent with the ecological setting into which they are released. Key environmental processes are dissolution, adsorption and chelation processes and biological action. The expected soil component responses might be recovery from cratering through organic matter inputs, and the assimilation and transformation of explosive compound contamination within the soil matrix. The spatial and temporal characteristics of munitions disturbance and important ecotype soil quality attributes were examined for an Army range impact area at Ft Greely, AK. Forty-eight control plots, twelve impact area plots, and five craters were examined. Cation exchange capacity (CEC) was highly correlated to soil organic matter (SOM) and there appears to be a significant gradient of soil quality characteristics for craters. Characterizing the distribution and dynamics of SOM may improve ecosystem management in the face of evolving contaminant threats. Once SOM for a particular system is characterized it can then be readily modeled and used as a resiliency metric for use in management decision models.

## Introduction

Munitions use on military lands is of keen environmental interest primarily due to the potential for contamination from unexploded ordnance (UXO) constituents. There has been little research on ecosystem response to munitions use. Demarais, et al., (1999) describe a wide array of spatial and temporal disturbance regimes and agents of disturbance associated with military training. They summarized the limited body of knowledge related to the live-fire training and its physical, chemical and biological effects on the environment. However, little is known of the ability or capacity of an impact area ecosystem to response to munitions disturbance. Munitions use in the Washington Impact area at Fort Greely, Alaska provides an opportunity to examine the effects of munitions use in an ecosystem as well as the ecosystem's response.

The objectives of this study are to:

- Examine the spatial and temporal characteristics of munitions disturbance.
- Describe and relate important soil quality response/capacity attributes that directly influence the ability of the ecosystem to influence the fate and transport of potential UXO contamination.
- Resolve these attributes into a measurable metric or indicator that can then be used to evaluate ecosystem response.

## Background: Impact Area Design, Disturbance Regime and Ecosystem Response

### *Impact Area Design*

Impact areas are the ground and associated airspace within a training complex used to contain fired, dropped or launched munitions and any resulting fragments, debris, and components (CEMML, 1999). The Army's Readiness Program requires that impact areas provide effective individual, crew, and unit live fire and maneuver proficiency training using the Army's current and projected modern weapons systems (AR 210-21, 1997, p.10). Therefore, impact areas reflect a mission-oriented design that is continually being updated to accommodate technological and doctrinal changes.

Impact area lands are more effectively utilized by grouping firing ranges so that safety danger zones (SDZ, i.e., the hazardous, three dimensional space along a line from the gun to the target to include areas around the gun and target) associated with individual weapons systems overlap. This not only reduces the area required for live fire training, but also minimizes the area contaminated by UXO. Additionally, impact areas are segregated from surrounding maneuver areas and from public and private lands to avoid unintentional contact with UXO, which can be physically hazards. They

are intended for indefinite use (AR 210-21, 1997, p.15) because of the challenges and uncertainties associated with clearing UXO. As such, they represent a potential source of environmental contamination either from UXO residues or from other sources such as sediment pollution caused by normal cratering effects. Therefore, current impact area design and management of older impact areas, incorporates a high degree of environmental planning that includes pollution prevention, and natural and cultural resource protection considerations (TC 25-1, 1991, p.3-4)

Impact area size primarily depends upon the size and type of units designated to use them. An U.S. Army installation usually accommodates approximately one Army division. Divisions typically consist of 10,000 to 15,000 soldiers and their equipment and they have different missions and organization such as light infantry, air borne, air assault, mechanized infantry and armor. For example, armored divisions are equipped with hundreds of armored combat systems such as tanks and infantry fighting vehicles, while light infantry divisions have no armored combat vehicle systems.

Combat readiness is a measure of a unit's ability to accomplish its assigned wartime mission. Many of the readiness capabilities assessed involve how well individual soldiers and combat crews employ their individual and crew served weapons systems. Therefore, Army range objectives are tailored to provide ranges and associated impact areas to ensure combat readiness of the division assigned to the installation (Table 1). Ranges are generally designed for direct fire or indirect fire weapons systems or for a combination of system types. Based on these range requirements, one can determine an approximate target and target array area requirements within an impact area for a given set of ranges. Direct fire weapons systems such as tanks and anti tank systems are those that fire to a point target such as an enemy tank or fighting position. They require a series of single targets each of which occupy a relatively small area on the order of a quarter hectare. Indirect fire weapons systems are those employed against area targets such as a group of enemy vehicles or soldiers. They require groupings of targets or target arrays that occupy a somewhat larger area on the order of one hectare. Typically, division sized range facilities and impact areas require on the order of one or two thousand targets and target arrays occupying many hundreds of hectares within impact areas.

The impact area that is the subject of this study is at Fort Greely located in Alaska. Fort Greely has been an active Army installation for over fifty years. The installation covers around 267,905 hectares and has 34,415 hectares of high hazard impact areas – those in which high explosive munitions are employed (Figure 1 and Landsat image at Appendix A). Its impact areas were designed to support a division-sized unit, although today only one brigade (approximately 25% of a standard division) trains at Fort Greely.

### *Anthropogenic Disturbance*

Munitions use and fire resulting from both munitions use and maneuver training are significant disturbance gradients operating at Fort Greely. An examination of the types of munitions used in an impact area, the quantities expended, and an approximation of the magnitude of potential contaminant loading provides a measure of the problem under consideration. High explosive munitions are the focus of this study because they have both a destructive and contaminate effect in the environment. High explosive munitions are those that explode on or near the ground and therefore have the potential of creating a crater. Other munitions include smoke projectiles, illumination projectiles, and small arms and inert projectiles (CEMML, 1999). These munitions have the potential of creating craters, but this potential is relatively small compared to high explosive munitions.

The magnitude of the physical disturbance occurring within Fort Greely impact areas can be approximated by an evaluation of munition expenditure data for the period 1992-1997 (Table 2 and Tabular Data for Munitions Loading at Appendix B). Fort Greely's high hazard impact areas had at least 185,846 high explosive munitions fired, launched or dropped into its impact areas or approximately 30,974 munitions per year (CEMML, 1999). To account for the area exposed to high explosive munitions, one can approximate the surface area of target arrays. This area could encompass up to 945 ha exposed to munitions disturbance, or about 2.75% of the total impact area lands. Determining the approximate annual cratered surface area refines this estimate of disturbance. Again, using the CEMML (1999) data set and assuming a crater radius for each type of munition it can be determined that approximately 10.21 ha were disturbed annually during this period representing approximately 1.08% of the lands exposed to munitions or less than 0.03% of the total high hazard impact areas.

In addition to the inherent kinetic and blast destructive effects of munitions, there is a little understood contaminant effect associated with munitions that fail to function properly. There are two modes of munition failure – dud and low order detonation. A dud is a round that completely fails to function at the target while a low order detonation is a round that only partially functions leaving part of the high explosive filler scattered over the target area (USATCES, 2000). Dud rounds retain their explosive filler inside the delivery body of the munition and are relatively isolated from the environment. However, during impact the delivery body can become fractured and over time there is the possibility that small amounts of explosive filler can be mobilized through dissolution with water. Low order detonations can result in significant amounts of ready availability explosive filler for dissolution and subsequent movement into the environment (Brannon et al., 1999). Therefore, both dud and low order detonation munitions have the potential for environmental contamination by leached explosive filler.

Explosive fillers such as Trinitrotoluene (TNT), Royal Demolition Explosive (RDX), and High Melting Explosive (HMX) are subject to environmental fate and transport congruent with the ecological setting in to which they are released. Release is contingent on dissolution rates and there have been a limited but varied number of

reported rates. Brannon et al. (1999) reported the dissolution fluxes for free solid to liquid phase. Their model considers dissolution flux critical for quantifying contaminant-loading rates. They report TNT has the highest rate at  $4,164 \mu\text{g cm}^{-2} \text{hr}^{-1}$ ; HMX has a rate of  $454 \mu\text{g cm}^{-2} \text{hr}^{-1}$ , and RDX's has the lowest dissolution rate at  $360 \mu\text{g cm}^{-2} \text{hr}^{-1}$ . Lynch et. al, (2001) report much higher rates of  $604,800 \mu\text{g cm}^{-2} \text{hr}^{-1}$ ,  $25,056 \mu\text{g cm}^{-2} \text{hr}^{-1}$ , and  $8294 \mu\text{g cm}^{-2} \text{hr}^{-1}$  for TNT, HMX and RDX respectively. They used weapons grade explosives and subjected samples to mixing, which may be more similar to particular environmental conditions such as free product exposed to surface water flow. Since dissolution is a function of interfacial surface area, temperature, and energy input (i.e. degree of fluid motion), they may have observed these higher rates due to relatively large energy input. Also, dissolution rates of pure explosive will differ from the rate of mixtures of explosives used in munitions (e.g., an artillery munition may have a mixture of TNT and RDX). This is because most manufacturing processes result in one explosive encapsulated within another explosive, or within compounds that serve as explosive binders. For example, "certain formulations include binders made of insoluble wax; explosives almost entirely encapsulated in wax would persist for extended periods of time yet yield comparably lower concentrations." (Lynch, 2001, personal communication).

The magnitude of the contaminant threat can be approximated by an evaluation of munition failure rates. Using failure rates published by USATCES (2000) and assuming the same failure rates are applicable to Air Force munitions, analysis indicates that there could be approximately 1,271 dud and 95 low order munitions failures per year on Fort Greely impact areas. Loading rates could be derived from this data, but the highly variable nature of the state of explosive fillers available for mobilization (e.g., fully contained in a dud delivery body, partially contained in a low order delivery body and/or scattered by a low order detonation) coupled with varying solubility and dissolution fluxes resulting from manufacturing processes makes any attempt very uncertain. The most conservative approach to assume that all of the explosive filler from dud and low order munitions failures is available for dissolution. Assuming, optimum dissolution conditions this results in a maximum potential annual average of  $4,460 \text{ kg}$  of high explosive materials and translates into a maximum theoretical loading rate within the target array area exposed to high explosive munitions of about  $0.46 \text{ gm m}^{-2} \text{ yr}^{-1}$ . Alternatively, assuming that this maximum potential annual average of high explosive materials is deposited in cratered areas, the maximum theoretical loading rate could be as high as  $44 \text{ gm m}^{-2} \text{ yr}^{-1}$  (Table 2). Assuming this load resides in the top 1 cm of the soil profile, a soil bulk density of  $2.0 \text{ Mg m}^{-3}$  (e.g., glacial till; Brady and Weil, 1999, p. 136), and that no transformations take place, this equates to potential concentrations ranging from  $0.046 \mu\text{g gm}^{-1}$  for target areas to  $4.4 \mu\text{g gm}^{-1}$  for craters for a given year. This is potentially well below Environmental Protection Agency residential risk based concentrations (i.e., 5.8 to  $3900 \mu\text{g gm}^{-1}$  for various explosives) reported by Walsh et al., (2001).

Finally, the other major form of human disturbance is in the form of fires started either by maneuver training or by munitions use. Jorgenson et al. (2001) report that fire frequencies and percent area burned are slightly higher than similar forest types in

interior Alaska. Since 1950, 1.2% of Fort Greely has burned annually whereas interior Alaska forestland has exhibited percent annual burn areas ranging from 1% between 1940 and 1970, to 6 % between 1970 and the present. This slightly higher percentage is consistent with the effects of military training (Demarais et al., 1999). Fire is significant in this landscape because it is the dominant process affecting succession (Jorgenson et al., 2001) and is ultimately important in any soil forming process.

#### *Soil, Climate and Hydrologic Ecosystem Component Response*

When considering ecosystem response in the face of disturbance one naturally thinks of the manner in which a disturbed system recovers. A measure of stability is the concept of resilience or the time it takes a system to return to a steady state following perturbation (DeAngelis et al., 1989). Climate, soils, hydrology, flora and fauna interact and affect energy, moisture, nutrient and disturbance gradients which in turn regulate the structure and function of ecosystems and their ability to rebound from disturbances (Jorgenson et al, 2001). High system resilience has been characterized in terms of high energy fluxes through food webs and short nutrient cycling times (O'Neill, 1976; DeAngelis, 1980, 1989; Harwell et al., 1977; and Loreau, 1994). In the case of impact areas, expected soil component responses might be recovery from cratering through organic matter inputs, and the assimilation and transformation of explosive compound contamination within the soil matrix. These responses should be intimately tied to biomass inputs, and to processes that influence nutrient availability within the soil component.

Fate and transport processes are continuously at work within the environment. Brannon et al. (1999) developed a conceptual model for fate and transport of UXO that provides a basis for a qualitative evaluation of the key processes at work in the environment. Their model outlined representations for soil, sediment, and water environments, described source term considerations, and developed descriptor formulations of key processes resulting in explosive contaminant mobilization, retardation, and transformation effects. With modifications, these key processes are dissolution, the initiating release mechanism described above; adsorption and chelation processes in soils, considered to be an important retardation mechanism; and biotic transformation, or for the purposes of this study biological action, consisting of metabolism by microorganisms and uptake by plants. Biological action is regarded as an important transformation mechanism (Comfort et al., 1995; Larson et al., 1998a; Pennington, 1988; Price et al., 1998; Brannon et al 1999; Pennington et al., 1999a; and Pennington et al., 1999b).

Applying this conceptual model into an Alaskan ecological framework involves relating process and effect to relevant ecosystem components and their governing ecological setting. For example, dissolution is the process by which TNT, RDX and HMX are dissolved by a solvent from free product to solutes. In this case, the solvent is water that is provided via the hydrologic cycle. The hydrologic cycle is an ecological component that determines the availability of water, and its relative importance is

governed by the ecological setting of the region in which UXO is located. In Fort Greely, water is available in an unfrozen form for relatively short time frames.

Adsorption is the process by which solutes move to and bind with a sorbent. This processes is reversible and is dependent on the partitioning affinity of the solute for either the solute or sorbent (LaGrega et al., 1994). For this analysis, the process is the movement or partitioning of dissolved TNT, RDX, and HMX to soil colloidal surfaces. Generally, soil colloidal surfaces, composed of clays and humic matter, are negatively charged. In the subsurface, adsorption is primarily a process of positively charged organic chemicals accumulating at these colloidal soil surfaces of which naturally occurring humic matter in soil plays a significant role (LaGrega et al., 1994). Therefore, the notable parameter for adsorption is colloidal content of the soil component. Colloid content can be measured via a soil's cation exchange capacity (CEC) which in turn is used to define a partitioning coefficient for contaminant to soil adsorption. In terms of the influence of ecological setting on the adsorption process, one can evaluate the soil quality and its CEC to obtain an indication of the relative retardation potential of the area in which UXO is found. Generally, Alaskan soils are not as weathered as soils in more temperate regions. Therefore they generally have less clay fraction and humus becomes the dominant contributor to CEC.

Adsorption of TNT to soil has been documented and considered to be very important in immobilizing TNT and its transformation products (Larson et al., 1998b; Pennington et al., 1999c; Comfort et al, 1995; Weissmahr et al., 1998; Myers et al., 1998) and in particular to humic soils (Hundal et al., 1997). TNT adsorption has been positively correlated with cation exchange capacity (CEC) of soils (Pennington, 1988; Brannon et al., 1999). RDX has been shown to sorb at lower rates than TNT (Singh et al., 1998; Price et al., 1998) and also can be positively correlated with soil CEC characteristics (Brannon et al., 1999). While HMX adsorption occurs, little is known about the solute-sorbent process to enable the prediction of adsorption coefficients for HMX (Brannon et al., 1999).

Metals availability are largely determined by the colloidal portion of soil organic matter (Tate, 1987). Humic acids contain highly reactive anionic groups that chelate or complex metals. Tate (1987) states that due to the high reactivity of these groups there is a positive relationship between degree of humification and complexation. This relationship should be less pronounced in acidic soils as may be the case in Alaska were coniferous forests intensify soil acidity.

Biological action consists of the mechanisms of biodegradation and bio-uptake of contaminants. Biodegradation involves the oxidation and reduction of organic contaminants and bio-uptake of organic and inorganic contaminants involves plant root uptake by vegetation. Both depend on the ecological components of soil and climate. Soil structure provides habitat for microorganisms, which obtain energy and carbon from the soil. Vegetation requires soil for structural support, for a source of oxygen for root respiration, and for a source of macro and micronutrients. Soil microorganisms and plants both require water and a temperature regime conducive for growth, which is a

function of climate. Soil organic carbon (SOC) content and climate in terms of effective growing season (EGS) are good indicators of conditions favorable for microbial and plant activity. SOC and EGS can provide a relative measure of the transformation potential of the region in which UXO is found. In Alaska, growing seasons are relatively short so biological activity may not be as great as in more temperate regions.

Biologically, TNT can undergo both aerobic and anaerobic degradation (Brannon et al 1999; Larson et al., 1998a; Pennington et al., 1999a) provided there are sufficient carbon and energy sources for microorganisms (Pennington et al., 1999b). RDX and HMX undergo biodegradation only under anaerobic conditions (Price et al., 1998; Comfort et al., 1995 as reported by Larson et al., 1998a). Vegetation also can act as a sink for explosive contaminants by root uptake (Larson et al., 1998a).

All of the explosives, as with any solute, can be transported by groundwater advection. These UXO fate and transport characterizations help to serve as the conceptual foundation for the development of a framework for the ecological assessment of impact area resilience.

### **Spatial and Temporal Scaling of Ecological Soil Evaluation**

An ecological soil evaluation is an examination of soil quality and of ecosystem response to disturbance. Therefore, this research effort is designed based on appropriate scaling of the soil component processes and of disturbance response. Also, as one begins to evaluate the ability or capacity of an impact area ecosystem to respond to munitions disturbance one must be concerned with the relevant spatial and temporal scales associated with impact area use. Therefore, the first step in this evaluation process is one that determines the appropriate spatial and temporal scales of interest relative to munitions disturbance and UXO contamination.

O'Neill et al. (1986) argue that a critical step in addressing any problem is determining the scale of observation. This allows one to focus on a particular organizational level characterized by a range of rates that can be segregated from higher and lower levels of dynamics thereby describing a system that is conducive to study the results of which are not confounded by indifferent dynamics. This approach is further supported by Wiens (1989) who states that the goal of an investigation should be to obtain a balance between extent and grain (i.e., the upper and lower limits of resolution respectively) in order to minimize the spatial variance of a process of interest. Ecological setting, munitions use effects, soil quality indicators and information management requirements are scalar-sieves that can be used to define appropriate scales of interest and relevant parameters. Ecological setting provides a general indication for appropriate upper level scaling rational. An examination of munitions use within an impact area helps to define the anthropogenic disturbance regime resulting in a higher degree of spatial and temporal resolution. Soil quality indicators help to describe relevant large-scale (i.e., local) processes and provide a refined indication for both spatial and temporal scaling in terms of ecosystem response. Finally, information

management requirements integrate all of these scalars into an investigative arrangement.

### *Ecological Settings*

The ecological settings, or the dominant ecosystem components of interest, are important in helping to determine spatial and temporal scales of interest. As described above, climate, soils, hydrology, flora and fauna are examples of ecosystem components. They interact and they affect energy, moisture, nutrient and disturbance gradients which in turn regulate the structure and function of ecosystems (Jorgenson et al., 2000) found within the boundaries of an impact area. They involve complex processes that demand a hierarchical approach designed to define the system of interest and the types of measurements and their interpretations taken on the system (O'Neill et al., 1986). This allows one to determine and focus on a component of interest and its range of variation. Components that have slower rates become background and components with faster rates are averaged out (O'Neill et al., 1986). Relevant components in this evaluation are climate, flora and soils.

The climate of the system determines the availability of liquid water, which will largely determine the potential for, contaminate mobilization (Brannon et al., 1999). Also, it is a major determinant in vegetative growth and soils development. However, it operates at spatial temporal scales that are at higher levels and at slower rates of change than the disturbance response phenomena of interest. Climate is therefore considered a background component.

Since the majority of the contaminant threat lies at or near the surface of the ground, the soil component is an important ecological setting for an impact area at Fort Greely. The flora component and the successional characteristics of the system are intimately tied to soil development and therefore soil component processes should be reflected at the forest stand level. If one considers the extent of the study to be the boundaries of the impact area and the major forest ecotypes that populate it, then the grain should be at a scale that minimizes spatial variance within these boundaries. With extent held as a constant scale would be held constant the grain would be scaled at the level of sub forest stand. This should be large enough to decrease between grain spatial variance within the extent of the study area.

### *Munitions Use in Impact areas – Levels of Disturbance*

Walker and Walker (1991), describe a hierarchy of disturbance scales in Arctic Alaska. They state that anthropogenic disturbances are generally on the microscale level ( $10^{-1}$  to  $10^6$  m $^2$ ), and that cumulative impacts are on the mesoscale level ( $10^6$  to  $10^{10}$  m $^2$ ). This is particularly true of munitions use in impact areas wherein munitions cause craters that range in size from less than a meter to several meters in diameter. Also, impact areas accommodate firing of weapon systems that have ranges on the order of tens of kilometers and must retain the effects munitions requiring several

hundred to thousands of hectares. Temporally, munitions use within impact areas falls within the natural disturbance frequency range between 1 and 1000 years (e.g., monthly use over a period of fifty years), and is within the same recovery timeframe. Therefore, an evaluation that is intended to examine munitions use over spatial and temporal scales of hectares to square kilometers and years to hundreds of years respectively, falls comfortably into a microscale to mesoscale spatial and temporal realm as defined by Walker and Walker (1991). Finally, these scales of observation lend themselves to data derived from satellite sensed data and surface surveys to examine anthropogenic effects such as cratering and ecosystem recovery.

### *Inherent Soil Quality Indicators*

Soil quality should be affected by munitions use primarily through physical disturbance. Contaminant fate and transport in soils is dependent on same soil chemical properties that influence nutrient availability and uptake by plants and microorganisms (Heil and Sposito, 1997). Therefore, an examination of significant physical, chemical and biological indicators and their associated processes will provide an indication of appropriate spatial and temporal scales of study.

Topp et al., 1997 describe several physical attributes of soil quality. Key among them is soil water transmission and soil strength. Soil water transmission capability determines the rate at which excess soil water drains out of the root zone and reflects system water availability and matter transfer potentials. It is described by the soil's saturate hydraulic conductivity with rates ranging from  $10^1$  to  $10^3$  meters/year for fine to coarse textured soils respectively (Topp et al., 1997). Soil strength is a function of cohesion and friction and is a soil's ability to resist shear breakage, which is potentially important in physical disturbance response. It can be assessed over short spatial and temporal scales of square meters and years. Both soil water transmission and strength can be related to soil texture (Topp et al., 1997).

Chemical attributes of importance include mineralogy, pH, buffer capacity, organic matter, and cation exchange capacity. They affect rates of reaction for processes such as soluble complex formation, adsorption, mineral dissolution, are relevant to plant growth, (i.e. available nutrient utilization, mobility of nutrient species, and diffusion processes) and are on the order of meters/year (Heil and Sposito, 1997). A notable biological input into the chemical system is humus in organic matter provides reactive colloidal adsorption sites for nutrient storage and in doing so affects cation exchange capacity (Heil and Sposito, 1997). Organic matter has transformation and colloidal production rates that range from a few years to centuries (Parton, 1996).

Gregorich et al. (1997) describe two primary biological indicators of soil quality. They are total organic carbon and nitrogen and are related to soil organic matter dynamics resulting from management practices such as tillage. Cratering effects of munitions can be related to tillage. Long term studies are required to observe

significant changes soil organic matter accumulation or loss. Associated spatial and temporal scales are on the order of hectares and tens to hundreds of years.

Overall, spatial and temporal scales of interest are bounded by physical, chemical and biological properties of the soil component. Chemical properties seem to be generally aligned with small spatial and temporal time scales relevant to plant growth. Physical properties are generally aligned with slightly larger scales. Biological indicators are somewhat larger than chemical and physical indicators, and on the order of hectares and tens to hundreds of years. Also, biological indicators are significant in that they represent a higher level of system dynamics controlling chemical and physical soil properties. Based on the discussion above, key indices for soil quality as they relate to munitions use may be:

- pH and Buffer Capacity
- Cation Exchange Capacity
- Nutrient Status (e.g., N, P, K)
- % Sand, Silt, Clay (Texture)
- % Organic Carbon and Organic Matter

### *Information Management*

Information management allows one to understand technological limitations and capabilities and at the same time helps to integrate relevant spatial and temporal scales into a system which is not confounded by higher and lower levels of dynamics. In effect, it allows us to determine sampling methodology and subsequent analysis. Sample plot size is a compromise between the area utilized by a typical target array, the spatial resolution of sensor and mapping software, and an area that is conducive to effective land management. A one-hectare plot size meets all of these conditions. Target arrays range in size from 100 m<sup>2</sup> for direct fire targets to 1-4 ha for indirect fire targets; one hectare equates to 12.3 pixels of Landsat TM data (28.5 m spatial resolution); filtered (i.e., a 3x3 or a 5x5 majority filter) thematic classifications of TM data resolve to approximately 0.7-2 ha; and one hectare is a universally used management unit. (Figure 2). Temporally, remotely sensed data can provide recent and timely information about disturbance and response. Finally, soil quality information can be easily obtained and readily assessed at these scales.

Ecological settings provide a macro scale perspective, which is critical to understanding higher lever background dynamics. Munitions use helps to further define the extent of the problem narrowing the range of spatial and temporal scales. Soil quality is dominated by process dynamics that operate at scales relevant to the grain of measure and represents a micro perspective. Information management allows one to realize a balance between higher and lower level of dynamics within technological capability.

## Methods

### *Study and Control Area Descriptions*

Fort Greely Military Installation is located in central Alaska approximately 160 km to the southeast of Fairbanks, near the city or Delta Junction. The installation covers approximately 267,900 ha and consists of the cantonment area, West Training Area and East Training Area. Fort Greely is a US Army training and testing installation with approximately 34,400 ha of high hazard impact areas. The Washington impact area is the subject of this study and is used for a variety of weapons testing and training involving mortar and artillery firing exercises, tank gunnery, and aerial bombing. Washington impact area is set in a rivierine floodplain and encompasses approximately 800 ha within the Delta River floodplain (Walsh, et al., 2001). At the south boundary of the impact area is a portion of the Washington Range (i.e., an area from which weapons systems are fired into the impact area). This area extends approximately 2.5 kms to the south, is very similar to the impact area and is a control area for the study. It is called the Washington Range control area (Figure 1).

The second control area Jarvis Creek control area is approximately 15 km to the east-north-east of the Washington impact area is used for maneuver training and is named for Jarvis Creek that runs along the training area's western boundary. The area is similar to Delta River in terms of direction of water flow, elevation, geomorphic units and ecotypes (Jorgenson et al., 2001).

Further description of control areas and study area can be made in terms of the dominant ecosystem components of the Fort Greely area, which are climate, physiography, hydrology and disturbance. The climate of Fort Greely as described by Bailey (1998) is Boreal Subarctic characterized by a great seasonal range in temperatures. While its climate is moist all year, Fort Greely has relatively small annual amounts of precipitation that is concentrated in warm months. Winter is the dominant season with cool short summers. Weather data covering 63 years from Big Delta FAA/AMOS AP, AK (500770) indicates that January is the coldest month with an average maximum temperature of -16.1C and average minimum temperature of -24.1C. July is the warmest month with an average maximum temperature of 20.8C and average minimum temperature 10.3C. Total average annual precipitation is 29.5cm with July having the highest monthly average of 6.7cm. Total average annual snowfall amounts to 111.3 cm with October having highest monthly average snowfall of 23.4cm. Average snow depth during winter is 10.2 cm with the month of February having the highest monthly average depth of 25.4 cm. Using the USACERL methodology (Diersing et al., 1990), Fort Greely's effective growing season is 25 May – 31 August (Figure 3).

The region's physiography is described as the Tanana-Kuskokwim Lowlands (CEMML, 1999). It consists of a broad depression north of the Alaska Range on top of coalescing outwash fans that spread northward. The area is generally underlain by

permafrost, however areas over deep gravels and/or on south facing slopes are relatively free of permafrost. Alluvium consists of porous gravel sands. The dominant geomorphic feature associated with the impact area and control areas is glaciofluvial sediment deposits from the past Delta Glaciation and from modern glaciers (CEMML, 1999). Flooding events are generally infrequent, as these areas are located primarily on inactive glacial-fluvial outwash deposits or in inactive floodplains of meandering and headwater streams. Soils are poorly developed Inceptisols, underdeveloped Entisols and Histosols. Both stream systems physiographies are classified as riverine and flat (Jorgenson et al., 2001).

The hydrology of both areas is similar and characterized by braided glacial streams over glacial outwash fans. Both the Delta River and Jarvis Creek flow generally northward from Alaska Range to Tanana River. Delta River, which runs through Washington Impact Area and Fort Greely, drains 4305 square kilometers and is 130 kilometers long. Its primary source is glacial melt water from the Alaska Range and is entrenched up to 60 meters into an alluvial fan. The Jarvis Creek, which runs through control area and Fort Greely, drains 96 square kilometers, is 65 kilometers long and is entrenched into same alluvial fan. It is an influent stream that is dry during the winter, and has high water during spring melt and summer rains (CEMML, 1999). Delta River and Jarvis Creek are perched above single aquifer with varying local confinement. They both streams lose some flow to the aquifer in winter. The groundwater table is less than 10 meters below Delta River and flows to the northeast (CEMML, 1999). Finally, the natural disturbance component for both areas consist primarily of fluvial and fire processes and wind erosion (Jorgenson et al., 2001).

### *Ecotype Descriptions*

Jorgenson et al., (2001) is the primary source for ecological description of Fort Greely. They utilized a hierarchical classification scheme to present three levels of ecosystem organization and descriptions for the Fort Greely installation, which are:

- Ecodistrict – (1:500,000 scale) Middle Tanana Floodplain Common Regional Ecosystem with the Delta River Floodplain, Jarvis Creek Floodplain sub districts.
- Eosection – (1:100,000 scale) Glacial Fluvial Outwash - Active-riverbed Deposit, Inactive-riverbed Deposit, Abandoned Riverbed, and Inactive Cover Deposit.
- Ecotype – (1:25,000 – 50,000 scale) areas within Fort Greely with homogeneous topography, terrain, soil, surface form, hydrology and vegetation.

Their ecotype descriptions are based primarily on physiography and vegetation structures with the vegetation type or successional stage the differentiating characteristics. They argue that this approach is effective at differentiating soil characteristics and vegetation composition and that the integration of these characteristics is useful in discriminating ecotypes that “may have different sensitivities to disturbance.” (Jorgenson et al., 2001, p.18) which is of particular interest for this evaluation.

The physiography for both areas described above are classified as riverine. There are five riverine ecotypes associated with the study and control areas. These are differentiated by their vegetative cover and consist of scrub, broadleaf forest, mixed forest and needleleaf forest ecotypes and are described below.

The scrub ecotype is what Jorgenson et al., (2001) describe as Riverine Dwarf, Low and Tall Scrub. Vegetation consists of a range of early successional scrub species that are highly variable and frequently includes: *Dryas drummondii*, *Populus balsamifera* saplings, *Shepherdia canadensis*, *Fragaria virginiana*, *Oxytopis campestris*, *Elaeagnus commutata*, *Potentilla multifida*, *Salix alaxensis*, *Potentella fruticosa*, *Alnus tenuifolia*, *Salix planifolia*, *Betula nana*, and *Calamagrostis canadensis*. Soil profiles range from stratified to massive gravel with occasional thin and sandy layers that lack organics to interbedded silts and sands with thin surface organic layers. These soils are generally well drained (i.e., moist) to excessively drained (i.e., dry) and exhibit activities that range from slightly alkaline to slightly acidic.

The broadleaf forest ecotype is what Jorgenson et al., (2001) describe as Riverine Broadleaf Forest. Vegetation consists of a range of early to mid successional broadleaf species. Open to closed canopies are composed of *Populus balsamifera* (occasionally mixed with *Populus tremuloides*), and *Picea glauca*. Understories consists of *Shepherdia canadensis*, *Potentella fruticosa*, *Dryas drummondii*, *Fragaria virginiana*, *Ceratodon purpureus*, *Astragalus* spp., *Geocaulon lividum* and *Linnaea borealis*. Soil profiles range from interbedded gravel, sand and silt, lacking in organics to interbedded silts and sands with thin surface organic layers. These soils are generally well drained (i.e., moist) to excessively drained (i.e., dry) and exhibit activities that range from neutral to slightly acidic.

The mixed forest ecotype is what Jorgenson et al., (2001) describe as Riverine Moist Mixed Forest. Vegetation consists of a range of intermediate successional broadleaf and needleleaf species. Closed canopies are composed of *Populus balsamifera*, *Picea glauca*, and/or *Betula papyrifera*. Understories consist of *Shepherdia canadensis*, *Dryas drummondii*, *Fragaria virginiana*, *Ceratodon purpureus*, *Alnus tenuifolia*, *Rosa acicularis*, *Geocaulon lividum*, *Linnaea borealis* and *Hylocomium splendens*. Mixed ecotype soils are similar to those of the broadleaf ecotype described above.

The needleleaf forest ecotype is what Jorgenson et al., (2001) describe as Riverine Gravelly Needleleaf Forest and Moist Needleleaf Forest. Vegetation consists of a range of late successional needleleaf species. Open to closed canopies is composed of *Picea glauca*. Understories consist of *Shepherdia canadensis*, *Solidago canadensis*, *Geocaulon lividum* and *Hylocomium splendens*, *Rosa acicularis*, *Ledum groenlandicum* and *Calamagrostis canadensis*. Soil profiles exhibit interbedded gravel, sand and silt layers, with thin surface organics. These soils are generally well drained (i.e., moist) to excessively drained (i.e., dry) and exhibit activities that are slightly acidic.

## *Research Hypothesis and Tests*

The primary objective of this study is to describe and relate important soil quality response/capacity attributes that directly influence the ability of the ecosystem to influence the fate and transport of potential UXO contamination. Given this objective, this study evaluates ecotype soil properties in undisturbed and disturbed setting. Stated in terms of hypotheses, they are:

1.  $H_0$ : There is no relationship between ecotype and soil quality.  
 $H_A$ : There is a relationship between ecotype and soil quality.  
**Test**: Soil samples among ecotypes and t-Tests on paired means of selected indices.
  
2.  $H_0$ : There is no relationship between munitions use on a target and soil quality in proximity to the target.  
 $H_A$ : There is a relationship between munitions use on a target and soil quality in proximity to the target.  
**Test**: Soil samples around target in concentric rings and t-Tests on paired means of selected indices.

## *Study Design and Execution*

This design and execution of this evaluation consisted of three phases:

1. Identification of study plots in the Jarvis Creek control area using a land cover classification.
2. Soil sample collection in the Jarvis Creek control area, the Washington Range control area and the Washington impact study area.
3. Soil sample processing, laboratory and statistical analysis.

### Phase 1: Land Cover Classification

Initial efforts centered on creating a thematic land cover classification of the control and study sites producing thematic maps of the Tanana watershed in the vicinity of Fort Greely, Delta Creek impact area, Washington Range impact area and the Jarvis Creek control area. The objective was to generate a land cover classification to achieve the highest level of accuracy for the general informational categories of scrub, broadleaf forested, needleleaf forested, mixed forested ecotypes associated with these areas. Study plots in the Jarvis Creek control area control site were selected using these maps.

Landsat 7 ETM+ images were reviewed using the USGS Earth Explorer web site (<http://edc.sns17.cr.usgs.gov>) using Latitude and Longitude coordinates (NW corner – 147.04.00W, 64.20.00N and SE corner – 145.23.00W, 63.39.00N) to obtain a listing of

metadata records for all available imagery of the area. Candidate images were reviewed based on the lowest available aggregate cloud cover and acquisition dates from June to early September to maximize temporal variability of vegetation growth for as many of the potentially present vegetation classes while at the same time avoiding snow cover at higher elevations. Additionally, the image had to be recent acquired (i.e., no more than 2 years old) in order to maintain a high degree of mapping confidence. A Landsat 7 ETM+ scene of the area taken on 10 September 1999 (path 67, row 15) with zero aggregate cloud cover was obtained through US Army Space Command (ARSPACE) Remote Sensing unit in Colorado Springs, Colorado and the Topographic Engineering Center, Fort Belvoir, Maryland.

Reference data for Fort Greely, Alaska was obtained from the US Army Corps of Engineers Cold Regions Research and Engineering Laboratory (CRREL), in Hanover, New Hampshire. They provided a draft report titled, "An Ecological Land Survey for Fort Greely, Alaska" authored by Jorgenson et al. (2000). Their field data was collected between 1996 and 1998 and consists of 253 surveyed reference points and 126 surveyed verification points that describe the major cover types found on the Fort Greely reservation.

The image file was copied from the CDROMs to a working directory. Using ERDAS Imagine 8.4, the image was display in viewer window. Header records, file statistics and histograms showed that the image was properly georectified. The scene was subsetted to capture the area of interest the Fort Greely reservation. At this point, no enhancement was made to the image to preserve the spectral reflectance characteristics of the pixels. The scene had cloud cover and cloud shadow in the southeastern portion of the image centered over the Washington impact area (Appendix A).

A supervised classification of the scene was made using the reference and verification data generated by CRREL (Jorgenson et al., 2000). Reference point data was converted into an Arcview cover, which was then brought cover into the Imagine viewer. Attribute information was obtained for each reference point using the same cover in an Arcview 3.2 environment. Using the Imagine region-growing tool for all seed pixels (Area constrained = 100 pixels and Euclidean Distance = 20), pixels were selected that corresponded to the appropriate cover type. These seed pixels were then used to grow training polygons of similar spectral reflectance. This procedure was repeated for all of the usable reference points. For significant cover types without reference points (e.g. bare exposed rock, glacier, snow, road, agriculture) training polygons were delineated based on a manual image interpretation of CIR composites of the September scene.

Informational categories are listed below:

Level 1 Classification	Level 2 Classification
Water	<ul style="list-style-type: none"> <li>• River</li> <li>• Pond and Lake</li> </ul>
Forest	<ul style="list-style-type: none"> <li>• Broadleaf</li> <li>• Needleleaf</li> <li>• Mixed</li> </ul>
Scrub	<ul style="list-style-type: none"> <li>• Scrub</li> </ul>
Gravel/Pavement	<ul style="list-style-type: none"> <li>• Roads</li> <li>• Bare Exposed Rock</li> <li>• Barrens</li> </ul>
Agricultural Land	<ul style="list-style-type: none"> <li>• Agricultural</li> </ul>

During this process, there was some overlap of training polygons of different reference classes. A best estimate of which polygon to use based upon a seed pixel's proximity to an edge signature. A polygon whose seed pixel was best encompassed by similar pixels (i.e., farthest from pixels of different color) was retained. Reference points associated with cloud and cloud shadows were not used. Upon completion of the training polygon selection process 68 polygons generated by seed pixels had been obtained along with 12 polygons generated by manual polygon selection for a total of 80 spectral classes. A maximum likelihood algorithm was used to classify the whole image based on the 80 training spectral classes. A signature separability analysis was performed on the spectral classes using the transform divergence method for all 1-6 bands of information. This generated 2,926 pair-wise comparisons. Using the best average separability and a cut off score of 1,200 (out of a possible 2,000) spectral classes that were similar were merged and poor signatures deleted bringing the training signatures down to 43 spectral classes. Like cover classes (e.g. Scrub 1 + Scrub 2 + ... Scrub *i*, etc) were then combined based on histogram evaluations using a recode process resulting in mapping set of 21 cover classes. Finally, these cover classes were recolored to better distinguish patterns. The classified image was processed with a 5X5-majority filter, which greatly enhanced its appearance (Figure 4).

From the maps of sampling areas of interest, over 100 one-hectare size discrete (i.e., non-overlapping and homogenous) sampling plots, including 15 per ecotype, were identified using a random point generator within ERDAS Imagine 8.4. These sampling plots doubled as verification points. The recommended number of verification points for large area classification should be approximately 50 per ecotype (Jenson, 1996). However, this represents an enormous sampling effort and may be significantly more than required due to the relatively small sampling area of the Jarvis Creek control area. Jenson (1996) suggests that the total number of verification points can be estimated by the formula for the binomial theory:

$$N = \frac{Z^2 (p) (q)}{E^2} \quad \text{where,}$$

*Z* is the standard normal deviate for the 95% two-sided confidence interval,

$p$  is the expected percent error,

$q = 100-p$  and

$E$  is the allowable error.

For this study,  $Z = 1.96$ ,  $p = 85\%$ ,  $q = 15\%$ , and  $E = 10\%$  yielding an  $N = 49$  points. This minimum number then would be allocated across the ecotypes of interest as well as any other cover type of mapping interest (e.g., open or barren areas). Using three ecotypes (i.e., scrub, broadleaf, and mixed) and a cover type representing gravel barrens and gravel roads, this equates to approximately 12 verification points per cover type which as mentioned above are the sampling plots. These sample plots were circular with a radius of 55 m for an area of one-hectare.

### Phase 2: Soil Sample Collection

Central to the sampling effort is the recognition that measurements of environmental phenomena such as soils or the presence or absence of a contaminant are generally characterized by great variability. In an attempt to limit variability and the associated uncertainty, as well as reduce the number of required samples, CRREL has developed a composite sampling protocol (Ramsey, 2001, personal communication). This method involves collecting numerous (i.e., fifty) incremental samples from a given area, compositing these incremental samples into one well mixed sample, then using this well mixed sample for all laboratory analysis to achieve a substantial reduction in the realized variability of the data set. Since contamination is relatively more variable than measures of soil component characteristics, a composting sampling approach should work well for soil property and subsequent soil quality assessment. Therefore, all field sampling for this research project employed this approach. Field sampling consisted of two investigations:

#### Investigation 1 – Control Area Characterizations:

The purpose of this investigation is to determine baseline levels of soil quality distribution related to undisturbed ecotypes (Scrub, Broadleaf Forest, and Mixed Forest) referred to in Research Hypotheses 1. Needleleaf Forest ecotype was not sampled due to limited field time, however nine plots was reconnoitered for verification purposes. As described above, the thematic classification for the control area along with a random start point generator was used to determine discrete sampling plots in the control site. Sampling plots were located and marked using a Garmin III+ GPS receiver. Each sample consisted of fifty randomly collected 40 gm incremental samples that were composited into one 2 kg soil sample for that particular plot. Samples were collected from the interface of the organic and mineral strata of the soil profile (i.e., the "O" and "A" layers respectively) within a 55-meter radius of the marked point (Figures 5a and b). These samples were air dried, sieved through a 4 mm mesh, mixed well, double bagged in plastic bags and submitted to the CSU Soils Laboratory. At each sampling plot the depth of the cumulative organic matter was determined by digging a small trench to the depth of the lowest organic horizon or 40 cm which ever was deeper. Additionally, elevation, slope and aspect, and vegetative cover descriptions were noted for each plot.

## Investigation 2 – Physical Disturbance in Washington Impact Area:

The purpose of this investigation is to determine soil quality in disturbed ecotypes and to characterize soil quality distribution around impact craters referred to in Research Hypotheses 2.

The sampling area around an impact crater consisted of five concentric rings radiating incrementally outward from the center of the target (Figures 6a and b). The incremental distance ( $l$ ) from the target array will be determined by dividing the diameter ( $D$ ) of the observed disturbed area by five (i.e.,  $l = D/5$ ) creating five concentric rings. These four points are the sampling locations for each ring. Within each of these rings, twenty 40 gm incremental samples were collected from the top 2 cm of the soil surface. These  $4 \times 15 = 60$  sub-samples will be composited into one 2.4 kg soil sample for that particular sample ring. These samples were air dried, sieved through a 4 mm mesh, mixed well, double bagged in plastic bags and submitted to the CSU Soils Laboratory. Finally, elevation, slope and aspect will be noted for each target array.

### Phase 3: Soil Sample Processing, Laboratory and Statistical Analysis

Standard methods were used to analyzed soil samples and are described in Table 3. Soil data and descriptive statistics is at Appendix C.

#### *Investigation 1 – Data and Analysis*

Twelve one-hectare composite samples were taken from each of the four undisturbed ecotypes (i.e., Washington Control are scrub ecotype and Jarvis Creek control area scrub, broadleaf, and mixed forest ecotypes). A series of random duplicate samples were evaluated to determine if there were significant differences in both sampling method and laboratory analysis. Statistical analysis focused on detecting significant differences between mean % organic matter and pH of paired ecotypes. Tests were performed using two-sample t-Tests assuming unequal sample population variances and utilizing an alpha = 0.5.

#### *Investigation 2 – Data and Analysis*

Data and descriptive statistics for the crater ring characterizations can be found at Appendix D. Six craters were sampled. Replicates were visually evaluated based on error bars derived from a 95% confidence interval of their means. Statistical analysis of the rings focused on detecting significant differences between mean % organic matter of paired rings. Tests were performed using two-sample t-Tests assuming unequal sample population variances and utilizing an alpha = 0.5.

## Results and Discussion

### *Land Cover Classification RS/GIS Accuracy*

Based on vegetative growth patterns, the classified image that appeared to satisfactorily classify cover types. The classified image appeared to emulate the transitions between river, barren, scrub, mixed forested, broadleaf forested, and needleleaf forested areas, and it seemed to accurately classified lakes and ponds and agricultural areas. Overall classification accuracy was 78.3% (Table 4). However, classification of three of the four riverine ecotypes was exceptionally accurate. Mapping of Scrub, Broadleaf and Mixed Forest ecotypes resulted in 100%, 90% and 89% User's Accuracy respectively and the Kappa statistics describing classified verses reference data were equally as good. Needleleaf Forest ecotype was not accurately classified due to confusion with the other three ecotypes. This was most probably due to verification interpretation of the dominant canopy present during sampling. Of note was the classification's ability to map scrub ecotype (User's Accuracy of 100%), which is the predominant ecotype of the Washington impact area and of other impact areas on Fort Greely.

This classification's usefulness may only extend to riverine settings since the preponderance of the verification points fell within riverine ecotypes. Also, the classification process grouped two or three forms of ecotypes (e.g., level 3 classification of three types of scrub vegetation) which could possibly have been labeled in further detail had additional information been available. Even so, this method may still be appropriate for impact area soil quality evaluations in other settings as long as larger scale ecosystem components such as physiography are held constant.

The use of remotely sensed data in the form of Landsat 7 ETM+ coupled with computer aided analysis for classification into a geographic information system appears to be a viable method of determining ecotype in a riverine setting. When soil quality is correlated with ecotype, it should be a practical method of inferring soil quality through the use of remotely sensed data for situations in which large inaccessible areas must be evaluated. Therefore, it should be of significant value in determining soil quality for similar investigations.

### *Indicators of Soil Quality*

A summary of statistical tests and results is at Table 5. Since adsorption and chelation are directly related to cation exchange capacity (CEC), and CEC is a function of the colloidal content contributed by both organic matter and clays, a regression of CEC on both % organic matter and % clay was performed to determine which was the dominant contributor. CEC proved to be highly correlated to % organic matter with 77% of the variability in CEC represented by % organic matter within the control areas and with 86% of the variability in CEC represented by % organic matter within the impact

area. Clay was not correlated with CEC. Therefore, % organic matter was used to evaluate soil quality. Additionally, soil pH affects CEC, so it too was used as an indicator of soil quality.

### *Soil Quality Characteristics of Undisturbed Ecotypes*

Statistical analysis of the Jarvis Creek control area ecotypes showed no evidence that % organic matter or pH was different among these ecotypes (Table 6). However, there may be soil quality variables that co-vary within ecotypes that may be used to detect significant differences between them. The Washington Range control area scrub ecotype % organic matter and pH were significantly different from each of the Jarvis Creek control area ecotypes. These results indicate that there may be a significant difference in the soil quality of the Jarvis Creek control area ecotypes and Washington Range control area scrub ecotype. This may have implications for the use of remotely sensed ecotype spectral signatures in assessing soil quality, but the results may have been better if the Washington range and impact areas were included in the classification process. Also, a level 3 classification may have resulted in better discrimination between different vegetative forms within ecotypes (e.g, differentiating between a scrub ecotype dominated by *Dryas drummondii* and one dominated by *Populus balsamifera* saplings). Soil quality differences between these forms may then be more pronounced.

### *Soil Quality Characteristics of Undisturbed and Disturbed Ecotypes (Craters)*

Comparison of undisturbed Washington Range control area scrub to the Washington Impact area scrub showed no significant differences in % organic matter and pH. There was a significant difference between soil quality of craters and sampled plots within the impact area as well as a significant difference between soil quality of craters and Washington Range control area scrub. Statistical analysis of the crater ring replicates showed that both sampling technique and laboratory analysis appear to be consistent and reasonably precise (Figures 7a-f). Soil nutrient values are the most variable, but key measures of adsorption capacity (i.e., CEC and pH) are very consistent. Data analysis shows that as one moves from the center of the crater to the outer most sampled ring there is a significant gradient of soil quality characteristics (Table 7). While adjacent rings do not show significant differences in % organic matter, there is a significant difference between rings 1 & 3, 2 & 4, and 3 & 5. This difference is apparent in graphs of % organic matter verses distance from the crater center (Figure 8 a-f).

This analysis shows that cratering is a significant physical disturbance within the impact area. If the frequency and intensity of this physical disturbance exceeds the capacity of the system to recover, the system may reach a threshold from which both recovery and capacity for contaminant attenuation is lost. Whether the disturbance regime has or will reach a critical resiliency threshold can be evaluated by comparing

crater age. Relatively higher concentrations of organic matter were found in the center of craters that were four years or older. This is a reasonable finding given the nature of the soil forming processes at work in the Washington Impact Area. Craters provide a depression that can capture wind blown leaves, silts and finer organic particulates, as well as seeds. They may also capture snow and serve as a moisture source for plant establishment. Most of the craters sampled had small balsam poplar saplings at their center (used to approximate the age of the craters). It appears that the physical disturbance and displacement of soil material eventually serves as a catalyst for organic matter additions assisting recovery. Also, the % organic matter of the surface soil appears to recover as shown by the flattening of the gradient curve on older craters.

## **Conclusion**

### *Follow-on Analysis*

A principle component analysis of soil properties may provide greater insight into other important ecotype associated soil properties. While the statistical methods used in this analysis did not detect a significant difference in the soil quality of undisturbed Jarvis Creek control area ecotypes for % organic matter, a principle component analysis may provide better resolution of differences. Also, the data may be better suited for non-parametric analysis.

CRREL gathered munitions contamination data for the Washington Impact Area during the same period this study gathered soil quality samples. Many of the CRREL samples were superimposed over soil quality sampling. The CRREL data should be available in early 2002. Again, utilizing a principle component analysis and non-parametric methods of analysis may yield additional findings. If contamination can be correlated with soil quality, in particular to an indicator such as % organic matter which appears to be a reasonably consistent metric across all sampling done in this study, then it may be possible to rate a given soil for its resilience and attenuation ability.

### *Development and Use of Soil Organic Matter Resiliency Metric*

The soil component performs the following functions: provides habitat for soil microorganisms, serves as an engineering medium and structural support for plants, acts to filters water resources, and serves as a nutrient bank for vegetation (Bradey and Weil, 1999). Quality soils have been described by their soil organic matter. Soil organic matter (SOM) is a principal element of the soil component affecting all of the above. SOM enhances microbial functions increasing energy flux and rate of nutrient cycling, which in turn aids degradation of organic compounds resulting in less soil and water pollution and greater plant production. SOM is the source of humic substances that can increased a soil's buffer capacity resulting in a more stable soil pH. SOM can increase water-holding capacity, which provides for greater plant production. SOM is the source

of non-humic substances that can increase aggregate stability, which means less soil erosion and less soil and water pollution. These same non-humic substances can provide increased adsorption and metal chelation capacity enabling the soil component to retain organic and inorganic pollutants, which also contributes to less soil and water degradation.

It is these properties, and in particular SOM's ability to influence the fate and transport of contaminants through an ecosystem, that provides the basis for future work. If one can characterize the distribution of SOM, predict its dynamics, and ascribe measures of its attenuation potential, then the implications for adaptive ecosystem management in the face of evolving contaminant threats may be profound. Resource managers and environmental scientists could adapt their activities to maximize this potential thereby mitigating or avoiding disturbances that are beyond an ecosystem's resistance and resilience capability.

Agricultural practices such as tillage, fertilization, pesticide application and cropping have been universally recognized as anthropogenic disturbances of varying degrees affecting ecosystem productivity. SOM is central to understanding the effects of these practices. This agricultural scenario can readily be adapted toward range and impact area ecosystem management. Recently, the National Research Council, (2000) has proposed that SOM should be widely recognized as an indicator of soil quality and productivity because of its ability to:

- provide a nutrient and energy source for soil biota
- improve soil structure by strengthening soil aggregates
- increase water holding capacity
- promote infiltration and reduce erosion
- increase cation exchange capacity
- chelate metals
- influence the fate and transport of pesticides

Also, SOM is considered the single most important indicator of soil health (Larson and Pierce, 1994). SOM measurable attributes are listed in Table 8 (Fenton et al, 1999). They provide a sensitive measure of SOM's contribution to an ecosystem's soil function.

#### *Means of Simulating Soil Organic Matter Dynamics*

Once SOM for a particular system is characterized it can then be readily modeled and used as a resiliency metric. The next step in exploring ecosystem resilience in the face of munitions disturbance is to use SOM dynamics output, or the fluxes in SOM pools as a result of natural and anthropogenic driving variables, to provide an established metric for determining an ecosystem's response to various management practices. The findings of this study should enable effective parameterization of such a simulation.

Table 1. Notional Range Requirements for US Army Installations (TC 25-8). Target and target array calculations are based on ranges descriptions in TC 25-8.

Range No*	Range Type	Firing Unit Size	Maximum Position Points or Lanes per Range	Army Range Objectives	Armor	Mech	Inf	Division**		Modified
								1	1	
6-1	CPQC/MPFQC	CO	15	Required	1	1	1	7	7	105
6-2	Multipurpose Indoor Range	CO	Throughput Dependent	Optional	2	2	1	1	1	110
6-3	Basic 25 meter Zero	CO	110	Required	2	2	1	1	1	110
6-4	Automated Field Fire	CO	32	See Note	***	***	3	3	3	96
6-5	Automated Record Fire	CO	16	See Note	***	***	***	7	7	112
6-6	Modified Record Fire	CO	16	See Note	2	2	1	1	1	144
6-7	Sniper Field Fire	PLT	4	Optional	1	1	1	12	12	48
6-8	Night Fire (Small Arms)	CO	35	Optional	1	1	1	2	2	70
6-9	Known Distance	CO	55	Optional	2	2	2	1	1	55
6-10	Machine Gun 10 meter	CO	20	Required	2	2	2	1	1	20
6-11	Multipurpose Machine Gun Transition	CO	10	Required	1	1	1	12	12	120
6-12	Multipurpose Gunnery Range	CO	6	TBD	1	1	1	7	7	42
6-13	Hand Grenade Familiarization Course	CO	4	Required	1	1	1	4	4	16
6-14	Hand Grenade Qualification Course	CO	6	Required	1	1	1	7	7	42
6-15	Grenade Launcher	CO	4	Required	1	1	1	1	1	28
6-16	Recoilless Rifle	CO	8	Optional	1	1	1	7	7	56
6-17	Light Antitank Weapon	CO	8	Optional	1	1	1	1	1	8
6-18	Scaled Range (1:30/1:60)	CO	4	Optional	1	1	1	10	10	40
6-19	Scaled Gunnery Range (1:5/1:10)	CO	4	Optional	1	1	1	10	10	40
6-20	Stationary Gunnery	CO	14	Optional	2	2	1	1	1	14
6-21	Antitank Tracking and Live Fire	CO	20	Required	1	1	1	0.5	0.5	10
6-22	Light Demolition	CO	2	Required	1	1	1	6	6	6
6-23	Infiltration Course	CO	2	Optional	1	1	1	0	0	0
6-24	Bayonet Assault Course	CO	4	Optional	1	1	1	10	10	40
6-25	Target Detection (Non-firing)	CO	50	Optional	1	1	1	0.2	0.2	10
6-26	MOUT Assault Course (MAC)	CO	8	Required	1	1	1	1	1	8
6-27	Gunship Harmonization	CO	1	Optional	1	1	1	1	1	1
6-28	Flame Operations Range	CO	6	Optional	1	1	1	6	6	6
6-29	Mortar, Scaled	CO	6	Optional	1	1	1	2	2	12
6-30	Motor	CO	6	Required	1	1	1	5	5	30
6-31	Field Artillery, 1:10 Scaled	BTRY	Optional	Optional	1	1	1	5	5	30
6-32	Field Artillery Indirect Fire	BTRY	Optional	Required	1	1	1	5	5	30
6-33	Multipurpose Training Range	CO	2 Trials	Required	2	2	1	20	20	40
6-34	Combat Engineer Vehicle	CO		Required				22	22	22
6-35	Air Defense Firing	BTRY		Optional	0	0	0	2	2	12
6-36	Helicopter Gunnery	CO	8	Required	1	1	1	3	3	24
6-37	Fire and Movement	CO	Throughput Dependent	Optional	1	1	1	6	6	24
6-38	Squad Defense Range	CO	5	Optional	1	1	1	6	6	30
6-39	Infantry Squad Battle Course	SQUAD		Required	1	1	1	20	20	20
6-40	Infantry/Platoon Battle Course	PLT		Optional	1	1	1	60	60	60
6-41	MPRC-H+	PLT		Required	1	1	1	60	60	60
6-42	MPRC-L+	PLT		Required				60	60	60
6-43	Platoon Defense Against Aircraft	BTRY		Optional	0	0	0	NA	NA	NA
6-44	MOUT CTF++	CO/BN	16/32	Required	1	1	1	NA	NA	NA

\* Range numbers correspond to those in Chapter 6, TC 25-8

\*\* Notional quantities by range type depend on annual training frequency. The most current DA PAM 350-38 prescribes training frequency.

\*\*\* AFs and AFRs are recommended for TRADOC school installations. MFRs are recommended at unit-based installations to conserve resources.

+ Type and configuration of MPRC selected depend on which units are supported (armour/mechanized division = MPRC-H; LD, air assault division = MPRC-L).

++ AC division installations typically need a MOUT complex consisting of a 32-building CTF with MOUT assault course to meet throughout METL training requirements. AC separate brigade, semiaactive installations supporting RC annual training and weekend training typically need a MOUT complex consisting of a 16-building CTF with MOUT assault course.

Table 2. Summary of area determinations and potential contaminant loading rates.  
Tabular data can be found at Appendix B.

	Acre	Hectare
<b>Ft Greely Installation Area</b>	<b>662000</b>	<b>267905</b>

## CLASSIFICATION ACCURACY ASSESSMENT REPORT

### ERROR MATRIX

Classified Data	Reference Data				
	Mixed Forest	Scrub	Needleleaf Forest	Gravel Pavement	Broadleaf Forest
Mixed Forest	8	0	1	0	0
Scrub	0	14	0	0	0
Needleleaf Forest	3	4	7	0	2
Gravel/Pavement	0	0	1	9	1
Broadleaf Forest	1	0	0	0	9
Column Total	12	18	9	9	12

### ACCURACY TOTALS

Class Name	Reference Totals	Classified Totals	Number Correct	Producers Accuracy	Users Accuracy
Mixed Forest	12	9	8	66.67%	88.89%
Scrub	18	14	14	77.78%	100.00%
Needleleaf Forest	9	16	7	77.78%	43.75%
Gravel/Pavement	9	11	9	100.00%	81.82%
Broadleaf Fores	12	10	9	75.00%	90.00%
Totals or Average	60	60	47	79.45%	80.89%

**Overall Classification Accuracy = 78.33%**

### KAPPA (K<sup>A</sup>) STATISTICS

**Overall Kappa Statistics = 0.7289**

Conditional Kappa for each Category.

Class Name	Kappa
Mixed Forest	0.8611
Scrub	1
Needleleaf Forest	0.3382
Gravel/Pavement	0.7861
Broadleaf Forest	0.875

Table 4. Error matrix, Mapping Accuracy and Kappa Statistics for Ecotype Classification

Table 5. Summary of Statistical Tests and Results. Detailed analysis is at Appendix D.

Hypothesis	Test	Results/Remarks
1. and 2. What independent variable (%Organic matter or %Clay) most affects Cation Exchange Capacity (CEC)?	Regression CEC on % Organic matter and %Clay	CEC-OM $R^2=.77$ CEC-Clay $R^2=.009$ Therefore, focus on % OM
1. Is there a difference between undisturbed ecotypes, for broadleaf, mixed and scrub?	t-test on % Organic matter and pH means	No evidence that the Jarvis Creek % OM means are different, Scrub W is different from all Jarvis Creek ecotypes
1. Is there a difference between Washington undisturbed and disturbed scrub?	t-test on % Organic matter means	There is no evidence of a difference.
2. Is there a difference between crater samples and impact area plots, and between crater samples and Washington undisturbed plots?	t-test on % Organic matter and CEC means	Significant difference between % Organic matter means, $p=0.03$ and $0.001$ respectively.
2. Is there a difference between crater ring replicates for crater rings?	Graph with error bars for selected analytes	Graphs of crater ring replicates with error bars (Figure 7a and b)
2. Is there a difference between rings for crater averages for crater rings?	t-test on % Organic matter means	Significant difference between means for Rings 1&3, 2&4, 3&5 (Table 7)

Table 6. Undisturbed ecotype analysis. Shaded blocks depict ecotypes for which there is no evidence of a difference between ecotype for % organic matter. "Scrub W" is Washington Range Control Area scrub and "Scrub J" is Jarvis Creek Control Area Scrub.

Summary of t-Tests % OM	Scrub W	Scrub J	Broadleaf	Mixed
No evidence to reject $H_0$ :				
Means are equal				

Table 7. Crater ring analysis in which common crater rings were averaged together. Shaded blocks depict rings for which there is no evidence of a difference between rings for % organic matter.

Summary of tests %OM	Ring 1	Ring 2	Ring 3	Ring 4	Ring 5
No evidence to reject $H_0$ : Means are equal					

Table 8. SOM attributes, measures and environmental effects summarized from (Fenton et al., 1999).

SOM Attribute	Measure(s)	Environmental Effect
Buffer Capacity	Buffer Capacity	Stable pH to aid adsorption
Water Holding Capacity	Bulk Density and Texture	Biomass production
Aggregate Stability	Bulk Density and Texture	Erosion Prevention
Adsorption Capacity	Cation Exchange Capacity and pH	Organic and Inorganic Adsorption
Chelation Capacity	Cation Exchange Capacity and pH	Inorganic Adsorption

# Study and Control Areas
